

# VOCs Gas Sensing

Subjects: Nanoscience & Nanotechnology

Contributor: Eleonora Pargoletti

Nowadays, the detection of VOCs at trace level (down to ppb) is feasible by exploiting ultra-sensitive and highly selective chemoresistors, especially in the field of medical diagnosis. By coupling Metal Oxide Semiconductors (MOS e.g. SnO<sub>2</sub>, ZnO, WO<sub>3</sub>, CuO, TiO<sub>2</sub> and Fe<sub>2</sub>O<sub>3</sub>) with innovative carbon-based materials (as graphene oxide) outstanding performances in terms of sensitivity, selectivity, limits of detection, response and recovery times towards specific gaseous targets (such as ethanol, acetone, formaldehyde and aromatic compounds) can be easily achieved. Notably, carbonaceous species, highly interconnected to MOS nanoparticles, enhance the sensor responses by *i*) increasing the surface area and the pores content, *ii*) favoring the electron migration, the transfer efficiency and gas diffusion rate, *iii*) promoting the active sites concomitantly limiting the nanopowders agglomeration; and *iv*) forming nano-heterojunctions. Herein, the aim of the present work is to highlight the nanocomposites features in order to engineer novel flexible, miniaturized and low working temperature sensors, able to detect specific VOC biomarkers of a human's disease.

Keywords: graphene oxide ; metal oxides ; gas sensing ; volatile organic compounds ; chemoresistor ; sensing mechanism ; medical diagnosis ; breakthroughs

## 1. Definition

A sensor can be defined as a device able to convert a target chemical or physical variation into an easily processable signal. The sensing element has to fulfill two different tasks: first, it has to interact with the target gas through various mechanisms, like surface adsorption, charge transfer or ionic exchange (*receptor* task); then, this interaction has to be transformed into a signal, as a change in the electrical conductivity or in optical transmission (*transducer* task). There is a variety of sensing devices that rely on different chemical or physical phenomena, among which we can find chemoresistors that are based on variation of Metal Oxide Semiconductors (MOS) resistance upon target gas interaction. Hence, materials possessing elevated electronic, optical, mechanical features alongside with desired flexibility and lightweight are required especially for medical diagnosis <sup>[1][2]</sup>. Indeed, human's breath is mainly composed by N<sub>2</sub>, O<sub>2</sub>, CO<sub>2</sub>, H<sub>2</sub>O, other inert gases, while the remaining small fraction consists of more than 1000 different volatile organic compounds (VOCs) at parts per million (ppm) to parts per trillion (ppt) <sup>[3][4]</sup>. Compounds with relatively high concentrations in exhaled breath include ammonia (median concentration: 833 parts-per-billion, ppb), acetone (477 ppb), ethanol (112 ppb), propanol (18 ppb) and acetaldehyde (22 ppb) <sup>[5]</sup>. Alongside, it is well known that many diseases are accompanied by characteristic volatile organic compounds (VOCs) emission. Therefore, their recognition can provide diagnostic clues, guide the laboratory evaluation, and affect the choice of immediate therapy.

## 2. Graphene Oxide-MOS Gas Sensors

Along with the exploitation of pristine graphene, another method recently explored is the coupling of the metal oxides with graphene oxide (GO) <sup>[6][7]</sup>. Due to its lower defective structure and many surface oxygen-containing functional groups if compared to Reduced Graphene Oxide (RGO), graphene oxide has not been studied as much up to now <sup>[8][9][10]</sup>. Nevertheless, GO was reported to possess excellent electrical and mechanical properties <sup>[11]</sup> and its p-type semiconductor character <sup>[12][13][14][15]</sup> can be exploited to form a p-n heterojunction with various n-type gas sensing semiconductors. Moreover, GO functionalities can be the anchor points for the controlled chemical growth of metal oxides, thus giving rise to well-integrated composite materials. Hence, in this section, we will review the main steps forward in the engineering of novel promising chemoresistors comprising the use of graphene oxide, whose performances in terms of detection limit, signal intensity, response and recovery times are listed in [Table 1](#).

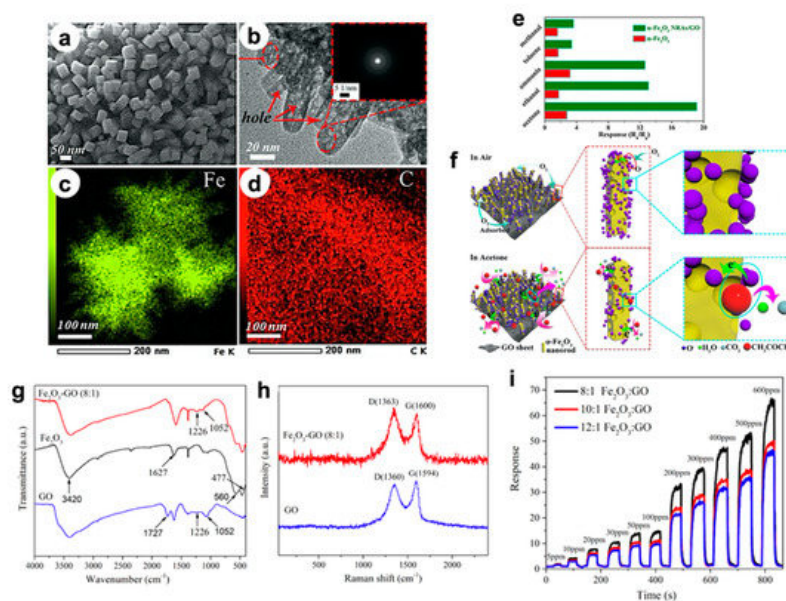

**Table 1.** A general comparison of graphene oxide (GO)-metal oxides (MOS) chemoresistors performances.

---

Metal oxide@GO	Synthetic Route	VOC	Operating T (°C)	LOD (ppm)	Response at LOD ( $R_{air}/R_{analyte}$ )	Response/Recovery Times (s)	Ref.
$\alpha$ -Fe <sub>2</sub> O <sub>3</sub>	In situ fluorine directed solution process/heat treatment	Acetone	220	5	< 10.0 <sup>a</sup>	7/8	[16]
$\alpha$ -Fe <sub>2</sub> O <sub>3</sub>	One-step low temperature hydrothermal	Ethanol	260	5	< 5.0 <sup>a</sup>	7/6	[17]
SnO <sub>2</sub>	One-step electrospinning	Ethanol	300	50	30.7	n.d.	[18]
Hierarchical SnO <sub>2</sub>	Electrospinning/hydrothermal	Formaldehyde	60	0.25	6.3	n.d.	[19]
SnO <sub>2</sub>	Hydrothermal	Ethanol	25 (UV)	0.1	1.7	310/320	[10]
SnO <sub>2</sub> -TiO <sub>2</sub>	Solvothermal	Acetone	200	0.25	6.3	10/12	[20]

<sup>a</sup> Extrapolated from the graph.

In particular, Song et al. [16] developed an in situ fluorine directed solution process combined with heat treatment to grow highly ordered, porous  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorod arrays (NRAs) on graphene oxide (GO) sheets, resulting in flexible 3D nanostructures. High-magnification SEM and TEM images (Figure 2a,b) display that both sides of GO sheets were fully covered by vertical nanorod arrays (~50 nm long and 10–20 nm wide), including the edges and wrinkle parts (see EDX analyses in Figure 2c,d). Remarkably, they observed nanopores inside the rods with sizes below 5 nm, which are believed to be beneficial for gas sensing. When tested with 50 ppm of acetone, the nanocomposite showed a high sensitivity at 220 °C, i.e., five times greater than that of pristine  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> (Figure 2e). Outstandingly, even after 50 days, a stable sensitivity was observed. Moreover, several target molecules were tested, resulting in a slightly higher selectivity towards acetone molecules. Therefore, the improved sensitivity, fast response/recovery and selectivity of the hybrid Fe<sub>2</sub>O<sub>3</sub> NRAs/GO was attributed by the authors to both the highly ordered, porous structure and the synergistic effect between  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and GO. Figure 2f reports a sketch of the possible sensing mechanism. At first, oxygen molecules adsorb on the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> NRAs and form O<sup>-</sup> species at the operating temperature of 220 °C. Then, acetone molecules react with O<sup>-</sup> species, inducing a material resistance variation, which is recorded by the sensing device.

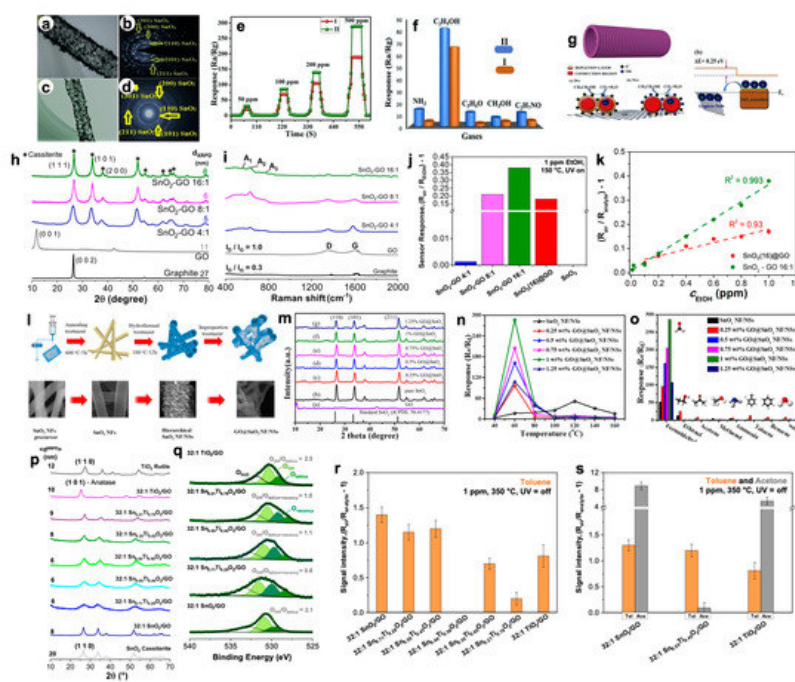

**Figure 2.** (a) SEM and (b) TEM images of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanorods array (NRAs)/GO hybrid. Energy Dispersive X-ray spectroscopy (EDX) elemental mapping images of (c) Fe and (d) C species, respectively. (e) Response of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> NRAs/GO and  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> nanoparticle-based sensors toward 50 ppm of different gases, at 220 °C. (f) Schematic illustration

of the gas sensing mechanism. Reproduced with permission from [16]. Elsevier, 2019. (g) FTIR spectra of GO, Fe<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>-GO (8:1) nanocomposites [17]. (h) Raman spectra of GO and Fe<sub>2</sub>O<sub>3</sub>-GO (8:1) samples [17]. (i) Response/recovery curves of Fe<sub>2</sub>O<sub>3</sub>-GO (8:1), Fe<sub>2</sub>O<sub>3</sub>-GO (10:1), Fe<sub>2</sub>O<sub>3</sub>-GO (12:1) nanocomposites towards 5–800 ppm ethanol, at 260 °C [17].

In addition, in Jia's et al. work [17], the authors investigated the same nanocomposite system based on Fe<sub>2</sub>O<sub>3</sub> grown onto GO via one-step low temperature hydrothermal method. Both FTIR and Raman spectroscopies confirmed the effective accomplishment of the GO decoration by iron oxide nanoparticles. In particular, infrared spectra of Fe<sub>2</sub>O<sub>3</sub>-GO (8:1) reported in Figure 2g show the characteristic band GO, such as C–OH stretching vibrations at 1226 cm<sup>-1</sup> and C–O–C (epoxy) stretching modes at 1052 cm<sup>-1</sup>; furthermore, the Fe–O vibrational absorption band at 560 and 477 cm<sup>-1</sup> are clearly observable. In addition, Raman spectra (Figure 2h) exhibit two characteristic peaks relative to D (~1360 cm<sup>-1</sup>) and G (~1594 cm<sup>-1</sup>) bands ascribable to the breathing mode of the *k*-point photons of A<sub>1g</sub> symmetry and the E<sub>2g</sub> vibration mode in GO. Notably, for the Fe<sub>2</sub>O<sub>3</sub>-GO (8:1), the relative D/G intensity ratio (ca. 1.07) is slightly higher than that of GO (0.94), confirming the more disordered structure of the nanocomposite, which may be due to the insertion of iron oxide nanoparticles into the GO nanosheets. Finally, the specific surface area of Fe<sub>2</sub>O<sub>3</sub>-GO (115 m<sup>2</sup> g<sup>-1</sup>) was around three times greater than that of pure iron oxide. Figure 2i displays the dynamic response of the nanocomposites with different Fe<sub>2</sub>O<sub>3</sub>-GO ratios towards ethanol (at 260 °C), resulting in 8:1 the best sensing material. The authors suggested that the improved performances are strictly connected, once more, to the larger surface area and incremental active sites. Hence, the results reveal that GO is crucial to improve the final gas sensing.

For what concerns the exploitation of tin dioxide material coupled with GO, several novel papers have recently been published. For instance, Seshendra Reddy et al. [18] prepared pure SnO<sub>2</sub> using the one-step electrospinning technique and GO-SnO<sub>2</sub> nanotubes (NTs) by dipping SnO<sub>2</sub> NTs into a GO solution followed by a suitable annealing treatment. HRTEM images along with the relative Selected Area Electron Diffraction maps of the hybrid sample revealed the effective GO wrapping on the surface of the SnO<sub>2</sub> NTs (Figure 3a–d).

**Figure 3.** HRTEM of (a) pristine SnO<sub>2</sub> (I) and (c) GO-SnO<sub>2</sub> (II) nanotubes (NTs) along with relative (b,d) SAED images. (e) Dynamic response of pristine and GO-SnO<sub>2</sub> NTs sensors towards 50–500 ppm of at 300 °C. (f) Comparison of sensing response to 100 ppm concentration of various gases at 300 °C. (g) Ethanol gas sensing mechanism of GO incorporated SnO<sub>2</sub> NTs in different atmospheres. Reproduced with permission from [18]. Elsevier, 2019. Structural properties by (h) XRPD and (i) Raman spectroscopies results relative to graphite, graphene oxide and hybrid SnO<sub>2</sub>-GO samples. (j) Comparison of response intensities towards 1 ppm of ethanol by adopting hybrid SnO<sub>2</sub>-GO 4:1, 8:1 and 16:1. For comparison, gas responses acquired with pristine SnO<sub>2</sub> and SnO<sub>2</sub>(16)@GO (physically prepared by mixing the two powders) samples were reported. Tests carried out in simulated air (80% N<sub>2</sub>-20% O<sub>2</sub>) at 150 °C, under UV light. (k) Linear correlation between sensors responses and ethanol concentration for mechanically prepared SnO<sub>2</sub>(16)@GO and SnO<sub>2</sub>-GO 16:1 compounds. (m) XRD patterns of GO, SnO<sub>2</sub> NF/NSs and GO@SnO<sub>2</sub> NF/NSs nanocomposites with different GO concentrations [19]. (n) Sensing responses toward 100 ppm of formaldehyde at different operating temperatures [19]. (o) Response of the gas sensors to different test gases at their respective optimal

temperature [19]. (p) Comparison of XRD patterns by increasing the Ti content into 32:1  $\text{Sn}_x\text{Ti}_{1-x}\text{O}_2/\text{GO}$  materials [21]. (q) XP spectra of O 1s region relative to three 32:1  $\text{Sn}_x\text{Ti}_{1-x}\text{O}_2/\text{GO}$  (with  $x = 0.71, 0.55$  and  $0.21$ ) as representative samples. Additionally, 32:1  $\text{SnO}_2/\text{GO}$  and  $\text{TiO}_2/\text{GO}$  were reported for comparison [21]. (r) Comparison of the response intensity of the solid solutions towards 1 ppm of toluene analyte [21]. (s) Comparison of the intensities at 1 ppm of toluene (orange) and acetone (grey) obtained with the most promising 32:1  $\text{SnO}_2/\text{GO}$ , 32:1  $\text{TiO}_2/\text{GO}$  and 32:1  $\text{Sn}_{0.55}\text{Ti}_{0.45}\text{O}_2/\text{GO}$  samples [21].

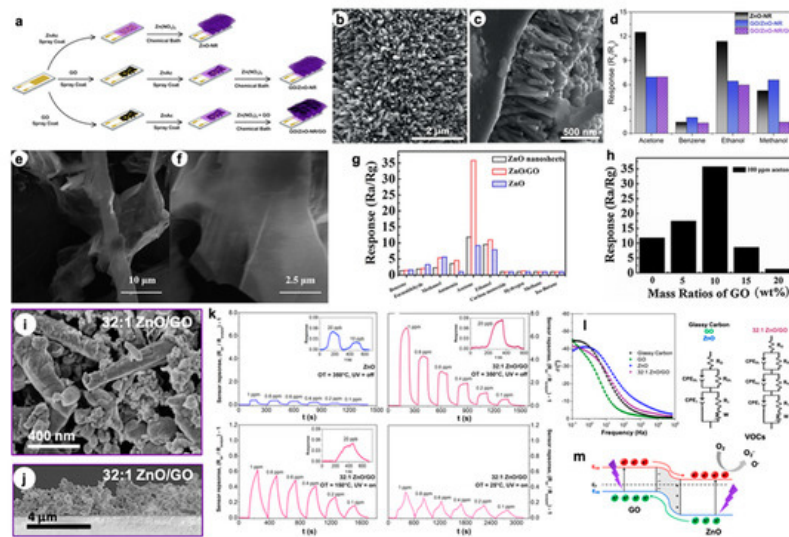

Moreover, in their work, the influence of GO on the ethanol vapor detecting performance of  $\text{SnO}_2$  NTs was analyzed in both dry and wet atmospheres. Figure 3e displays that the GO– $\text{SnO}_2$  nanotubes showed good response ( $R_a/R_g$  of ca. 85) towards 100 ppm of ethanol with an optimum working temperature of 300 °C in dry atmosphere. A slight decrease in the sensor signal (ca. 52) was obtained in wet atmosphere, performing better than pristine tin dioxide nanotubes. Furthermore, it is very selective towards ethanol with respect to other gaseous species (Figure 3f). The authors hypothesized the possible mechanism (displayed in Figure 3g), highlighting the role played by GO. Indeed, the graphene layer attached to the  $\text{SnO}_2$  NTs is believed to enhance the surface area and provide more chemisorbed oxygen on the material surface. In addition, GO stops the agglomeration of tin dioxide nanotubes, guaranteeing a higher active surface area. This could have led to significantly enhanced gas sensing properties. A deeper investigation of the coverage of GO by tin dioxide nanoparticles and the relative ethanol sensing performances were recently evaluated by Pargoletti et al. [10]. The authors of this paper finely investigated different  $\text{SnO}_2$ –GO ratios from 4:1 to 16:1 (by a simple hydrothermal method) from different physico-chemical points of view. The structural analyses reported in Figure 3h,i exhibit the effective gradual coverage of GO sheets by  $\text{SnO}_2$  nanoparticles. Moreover, sensing tests towards ethanol species showed that 16:1 ratio is the optimal one in terms of sensitivity, higher signals intensity, good response linearity by reducing the VOC concentration (Figure 3j,k), even with respect to mechanically prepared  $\text{SnO}_2$ –GO, namely  $\text{SnO}_2(16)@\text{GO}$ , and detection at lower operating temperatures (i.e., 150 °C, by exploiting the UV light).

In addition, Wan et al. [19] reported a formaldehyde gas sensor with highly sensitive and selective gas sensing performances at low temperatures based on graphene oxide (GO)@ $\text{SnO}_2$  nanofiber/nanosheets (NF/NSs) synthesized by electrospinning technique followed by a hydrothermal step (Figure 3l). Figure 3m shows the XRD patterns of pristine  $\text{SnO}_2$  NF/NSs, GO@ $\text{SnO}_2$  NF/NSs nanocomposites and GO. Notably, the diffraction peaks of tin dioxide do not change after introducing GO nanosheets, whereas the main diffraction peaks of GO are not perceivable due to its low loading. Indeed, the sensing performances of GO@ $\text{SnO}_2$  NF/NSs nanocomposites was optimized by adjusting the loading amount of GO, ranging from 0.25% to 1.25%. The results show the optimum loading amount of 1% not only exhibited the highest sensitivity value, but also lowered the optimum operation temperature from 120 °C to 60 °C (Figure 3n). Moreover, the GO@ $\text{SnO}_2$  NF/NSs showed a lower detection limit of 0.25 ppm and an excellent selectivity (Figure 3o). The enhanced sensing performances was believed to be mainly due to the high specific surface area, suitable electron transfer channels and the synergistic effect of the  $\text{SnO}_2$  NF/NSs and GO nanosheets network.

Finally, in Kalidoss's et al. work [20], a ternary composite based on  $\text{SnO}_2$ – $\text{TiO}_2$ –GO materials was reported. The gas sensing properties of the as-prepared GO– $\text{SnO}_2$ – $\text{TiO}_2$  nanocomposites films were investigated at the optimal temperature of 200 °C. The ternary compound exhibited superior gas sensing performances towards acetone in the range 0.25–30 ppm and was also an excellent candidate for the selective detection of this analyte in diabetes mellitus breath. As a step forward from this work, Pargoletti et al. [21] deeply investigated the coupling of  $\text{SnO}_2$ – $\text{TiO}_2$  solid solutions with GO (with 32:1 solid solution/GO weight ratio) to unravel the possible boosted selectivity of the prepared compounds towards aromatic species. A fine tuning of the Ti content into a  $\text{SnO}_2$  matrix was obtained, as clearly represented in the XRD patterns, resulting in an increased crystallinity due to a rise in particle size attained at high Ti content, i.e., at the phase transition from cassiterite-like to rutile-like crystal structure (Figure 3p). Remarkably, with the increase in Ti amount, a higher lattice defectivity was seen, corroborated by X-ray photoelectron spectroscopy (XPS) analyses. Indeed, focusing on the O 1s region (Figure 3q), the band relative to loss of oxygen or creation of oxygen vacancies is visible in the 32:1  $\text{Sn}_x\text{Ti}_{1-x}\text{O}_2/\text{GO}$  nanocomposites. Notably, these compounds were revealed to be more sensitive and selective towards toluene molecules at 350 °C (3r,s). The authors hypothesized that a low titanium content limits the cross-sensitivity to relative humidity by reducing the number of rooted and terminal hydroxyl surface species with respect to both pure metal oxides, thus becoming less hydrophilic and, hence, more prone to sense non-polar molecules as toluene ones.

In parallel to the tin dioxide semiconductor, ZnO-based materials have also been widely studied in the gas sensing field. Vessalli et al. [21] recently described an innovative synthetic route to grow ZnO nanorods (ZnO-NR) with controlled size and morphology on gold interdigitated electrodes (IDEs) via chemical bath deposition, at mild temperatures (90 °C; see Figure 4a).

**Figure 4.** (a) Synthetic route used to prepare ZnO-NR, GO/ZnO-NR and GO/ZnO-NR/GO samples. SEM image of (b) GO/ZnO-NR and (c) cross-section micrograph of the ZnO-NR arrays. (d) Comparison of the responses of ZnO-NR, GO/ZnO-NR, and GO/ZnO-NR/GO to 200 ppm of different VOCs (at 450 °C). Reproduced with permission from [22]. Elsevier, 2016. (e,f) FESEM images of ZnO/GO nanocomposites. (g) Sensing responses of pure ZnO, ZnO nanosheets and ZnO/GO nanocomposites sensors to 100 ppm of different gases, at 240 °C. (h) Responses obtained with different GO mass ratios in the ZnO/GO nanocomposites (100 ppm acetone, at 240 °C). Reproduced with permission from [23]. Elsevier, 2016. SEM image of (i) 32:1 ZnO/GO and (j) relative cross-sections of deposited layers [24]. (k) Dynamic responses towards various ethanol concentrations, by decreasing the operating T (at 150 °C and RT, exploiting the UV light) [24]. (l) Electrochemical Impedance Spectroscopy (EIS) Bode plots with corresponding fitting circuits [24]. (m) Schematic model of GO-ZnO p-n junction for hybrid materials under UV and with +1.0 V applied bias ( $E_{VB}$ ,  $E_{CB}$ ,  $E_F$  are energies of Valence Band, Conduction Band and Fermi level) [24].

Furthermore, through the same technique, ZnO-GO compounds were obtained in which graphene oxide sheets can be present below (GO/ZnO-NR) or on both sides of ZnO-NR (GO/ZnO-NR/GO), like a sandwich. The morphology of the as-obtained materials was deeply studied by SEM analysis. Particularly, from the cross-section image in Figure 4c, it is possible to determine the NRs length of about 640 nm. Conversely, the presence of GO in GO/ZnO-NR sample has led to larger diameters (Figure 4b) and the further increase in GO (GO/ZnO-NR/GO compound) caused the coverage of the ZnO surface by the graphene material itself. These structures, then, were tested as sensors for volatile organic compounds such as acetone, benzene, ethanol and methanol in the concentration range of 10–500 ppm, at the optimal operating temperature of 450 °C (Figure 4d). Notably, both the pure ZnO-NR and the GO/ZnO-NR/GO composite showed better selectivity towards acetone molecules, thanks to the either the peculiar morphological features or the presence of GO functional groups that favor the interaction with the target polar VOC. In addition, Wang et al. [23] finely explored the effect of GO content in the ZnO matrix on the final sensing. Specifically, both bare and phosphorus-doped ZnO nanosheets were produced by the CVD method, and GO was introduced by simple impregnation, adopting different graphene oxide amounts. FESEM micrographs reveal the presence of trigon-star like-shaped pure ZnO nanoparticles with branch lengths of around 5  $\mu\text{m}$  that tend to become smooth after P doping (Figure 4e,f). The nanosheets lengths are around tens of micrometers, several micrometers wide and around 50 nm thick. The authors found that 10 wt% GO is the optimal loading to reach very high responses ( $R_a/R_g$  of around 36) towards 100 ppm of acetone (Figure 4h). Moreover, this material seems to be the best performing one in terms of selectivity to acetone molecules, as reported in Figure 4g. The composite unique sensing properties are believed to be due to the presence of planar GO sheets, which offer an extensive 3D network, thus enhancing the interconnectivity among the ZnO nanosheets. In addition, defects and functional groups on the GO surface act as high-energy adsorption sites for the gas molecules and they can increase the final response. Nevertheless, for higher GO content (more than 10 wt%), partial ZnO nanosheets are covered by graphene oxide, affecting the active interacting area of ZnO and acetone gas. So far, studies concerning the enhancement of the sensing features mainly at high working temperatures have been reported; however, to be used in portable devices, such chemoresistors should operate at low temperature. In this context, Pargoletti et al. [24] recently described novel ZnO-GO 3D nanonetworks which are able to sense different VOCs at room temperature, by exploiting the UV light. In addition, in the present work, the authors deeply investigated the optimal ZnO/GO ratio in order to get the best sensing performances, resulting in the 32:1 ZnO salt precursor-to-GO weight ratio being the most promising one. By adopting a simple hydrothermal method, the gradual coverage of GO sheets occurred, as clearly observable in Figure 4i, since with the lowest ratio (4:1) the characteristic GO morphology was still visible. Once synthesized, the nanopowders were deposited by an innovative hot-spray method giving rise to micrometric and highly porous (> 90%) films onto IDEs (Figure 4j).

Remarkably, only with the 32:1 ZnO/GO material was a successful signal towards different VOCs (such as acetone, ethanol and ethylbenzene) recorded down to RT by exploiting the UV light. Nevertheless, this nanocomposite showed a higher selectivity towards small and polar analytes, such as ethanol, for which 100 ppb were detectable even at RT (see Figure 4k). Therefore, the unique features of these hybrid compounds were finely investigated to understand their sensing mechanism. For this reason, electrochemical impedance spectroscopy (EIS) was adopted to possibly unveil the synergistic effect of GO and n-type semiconductors, like zinc oxide. Figure 4l exhibits the Bode plots of both chemically obtained compounds and mechanically mixed ZnO/GO with the same 32:1 ratio. Only with the 32:1 ZnO/GO was it possible to observe the presence of a third circuit relative to the heterojunction occurrence at the interface between graphene oxide (p-type) and ZnO (n-type) materials. This p-n nano-heterojunction could lead to boosted sensing properties, since an increased electron concentration is present in the conduction band of ZnO, thus favoring a risen amount of negatively charged oxygen species adsorbed onto the sensor surface (Figure 4m). Indeed, these species are believed to be the main protagonists of the sensing mechanism, according to the already described ionosorption model [25][26].

### 3. Conclusions and Future Outlooks

In recent decades, carbon-based materials, such as graphene, its derivatives (GO and RGO), and Carbon Nanotubes (CNTs), have been adopted as new platforms for the design of innovative metal oxide-based chemoresistors showing boosted sensing features. Indeed, thanks to their peculiar properties, such as their unique optical, electrical, mechanical, and thermal properties, they do help the sensitive, selective and lower temperature detection of VOCs. Indeed, the current research attention has been focused on the detection of ppm or even ppb concentrations of several volatile organic compounds (like ethanol, acetone, formaldehyde and aromatic compounds), since they are believed to be specific biomarkers of certain human diseases. Hence, their quick detection can represent a useful step for early medical diagnosis. Thus, in the present review, we have summarized the main breakthroughs in the engineering of nanocomposites exhibiting excellent sensing behavior in terms of optimal detection limits, selectivity towards specific VOCs, even under humid atmosphere such as a human's breath. Nevertheless, the majority of the materials recently investigated still have some shortcomings, especially related to the high operating temperatures that hinder their application in portable devices. To overcome this issue, the solutions can include (i) the synthesis of hierarchical, highly porous 3D materials to enhance the active surface area; (ii) the formation of p-n nano-heterojunctions, helping to increase the final signals; and (iii) the exploitation of different light sources (such as UV, solar or LED ones) to activate the material enabling the sensing at low T. Figure 5 shows that among the investigated carbon-based hybrid chemoresistors, the above-mentioned GO in combination with MOS represent a possible candidate for detecting VOCs (constant concentration, 10 ppm) at low operating temperatures. Furthermore, thanks to their flexible structure, graphene-based materials can be easily implemented in miniaturized hand-held devices. Low temperature-operating gas sensors will persist in representing an exciting challenge in the actual era of applications demanding the use of portable systems for point of care diagnosis and so on.

**Figure 5.** Schematic representation of sensing performances according to the relative optimal operating temperature for the four class of hybrid materials: graphene (G), graphene oxide (GO), reduced graphene oxide (RGO) and carbon nanotubes (CNTs) towards 10 ppm of several VOCs (EtOH = ethanol; Ace = acetone; For = formaldehyde; TEA = triethylamine; Ani = aniline). References have been added in brackets.
