Molecular Sensing with Hyperpolarized 129Xe

Subjects: Applied Chemistry
Submitted by: Jabadurai Jayapaul

Definition

Hyperpolarized noble gases have been used early on in applications for sensitivity enhanced NMR. 129Xe has been explored for various applications because it can be used beyond the gas-driven examination of void spaces. Its solubility in aqueous solutions and its affinity for hydrophobic binding pockets allows "functionalization" through combination with host structures that bind one or multiple gas atoms. Moreover, the transient nature of gas binding in such hosts allows the combination with another signal enhancement technique, namely chemical exchange saturation transfer (CEST). Different systems have been investigated for implementing various types of so-called Xe biosensors where the gas binds to a targeted host to address molecular markers or to sense biophysical parameters.

1. Introduction

Despite its excellent molecular specificity, NMR has strong limitations for many applications due to its low sensitivity at physiological conditions. The Boltzmann distribution around room temperature yields detectable magnetization for Faraday induction only if the spin densities are relatively high. This limitation is an even greater challenge for MRI and has been an active field of research for a long time. In this regard, the use of hyperpolarization techniques has opened up new possibilities in medical imaging diagnostics [1][2]. These techniques are key contributions to unleash the full analytical and diagnostic potential that is inherent to the NMR signal, particularly in biomedical applications. Conventional contrast agents act as relaxivity agents on the bulk water pool. They often require (a) relatively high concentrations (e.g., 10–100 µM for Gd-based T₁ agents) and (b) come with limited specificity. The strong background signal of ubiquitous tissue water is also of concern for certain applications. It can be addressed by detecting nuclei other than the abundant ¹H. Fluorine (¹⁹F) NMR has been used in many studies [3] as a background-free option but still does not solve the sensitivity issue with regard to minimum detectable concentrations. The hyperpolarization of various nuclei, incl. ³He, ¹³C, ¹⁵N, ¹²⁹Xe has thus attracted much attention over the recent years.

Hyperpolarized (hp) reporters based on ¹³C and ¹⁵N detection rely on covalently bound NMR-active atoms. They are used for real-time metabolic imaging to follow conversion of a metabolically active tracer (e.g., ¹³C-labelled pyruvate) for visualizing the Warburg effect in oncology applications [1][4][5] or for visualizing metabolic turnover in the heart [6][7][8]. The noble gases He and Xe, however, have been used in rather different contexts as they are not part of any biologically relevant molecules. Hp ³He has been applied early on for diagnostic lung imaging but is increasingly replaced with ¹²⁹Xe for such purposes [9]. Contrary to He, Xe has a decent solubility in aqueous solutions and has thus also been used in structural biology studies to explore cavities in proteins [10]. Moreover, the investigation of porous materials also benefits from Xe NMR studies where the nucleus is sensitive to interactions with the wall material [11]. Thus, despite being an inert gas, ¹²⁹Xe is a valuable diagnostic and biomolecular reporter for exploring its molecular environment [12][13] as it combines high sensitivity with high specificity. Its affinity to certain molecular environments has fostered further applications of hp Xe in which tailored host structures are utilized for detection through supramolecular inclusion complexes. Hp ¹²⁹Xe NMR also displays a broad chemical shift range of about 300 ppm related to xenon's large polarizable electron cloud. This large chemical shift range of Xe enables sensing of different chemical environments under biological solutions with high sensitivity. Many different bound Xe resonances are clearly separable within this chemical shift range and thus promote simultaneous detection of various Xe environments. This motivated the so-called "multiplexing" approach in analogy to different dye-based optical imaging [14][15]. Nanocarriers with Xe affinity have been...
designed to enable sensitivity-enhanced NMR of otherwise undetectable spin density. Such targeted Xe hosts are summarized as functionalized Xe biosensors that were first pursued by the Pines and Wemmer labs. They have evolved over the past 20 years in different designs with constant improvement in sensitivity. A major step was the combination with indirect detection through saturation transfer, a concept that had also consequences for optimized host design.

Xe biosensors have now been implemented for many different biological targets and their molecular properties have been studied under various conditions. As the concept moves towards preclinical applications, certain criteria have been identified to unleash the full potential that this method has shown in in vitro experiments for translation into biomedical diagnostics.

2. Xenon-Host Interactions: The Basis for Functionalized $^{129}$Xe NMR

As a gas, Xe is a straightforward reporter for investigating cavities in porous materials. Its application range, however, goes far beyond synthetic structures. Various proteins also have an affinity for Xe. Their complexes with the noble gas have been investigated in X-ray crystallography where Xe serves as a heavy element surrogate probe for O binding sites in gas binding proteins. The non-polar, inert guest can be a very powerful probe to explore host cavities that are otherwise occupied by guests but that do not yield a useful reporter signal. Together with its large chemical shift range as a consequence of its large polarizable electron cloud, Xe is a highly sensitive NMR reporter for cases where transient binding occurs. Identifying suitable host structures is a key step in designing Xe biosensors and various designs have been proposed. Importantly, both the binding affinity and the exchange kinetics are relevant for efficient molecular sensing.

3. Production and In Situ Delivery of hp Xe

The Zeeman splitting of nuclear spin states is a minor energy correction term in technically achievable external fields. While this is an advantage with respect to the harmless RF irradiation that is used to acquire NMR/MRI data, it has major consequences for the achievable spin polarization at room temperature. Under thermal equilibrium conditions at ~300 K, the high temperature approximation applies and the system provides a rather minute "thermal polarization" in the presence of an external magnetic field. Thus, the NMR signal of dilute molecules is only detectable after extensive signal averaging and rather low SNR values. A higher concentration of the molecule of interest is typically unavoidable in order to achieve the desired NMR signal under thermal polarization conditions. To boost NMR sensitivity and to rapidly acquire signals with high SNR, hyperpolarization (hp) is actively being utilized for different reporter molecules. In hp conditions, the nuclear magnetization is artificially enhanced prior to the NMR experiment. Generally, the process provides $10^3$-$10^5$ fold higher signal enhancement compared to the thermal polarization. Electromagnetic radiation on the nuclear Larmor frequency cannot be used to directly overpopulate a spin state. Instead, all hyperpolarization techniques have in common that they rely on a precursor system that is polarized in a first step before the polarization is transferred onto the detected nuclei. Two of the common hp approaches, DNP (dynamic nuclear polarization) and PHIP/SABRE (para-hydrogen induced polarization/signal amplification by reversible exchange), polarize covalently bound nuclei and thus the delivered tracer is part of the entire polarization procedure. Conversely, hyperpolarized $^{129}$Xe gas can be generated without being covalently bound to the (indirectly) detected molecular structure.

Xe biosensors particularly rely on the concept that, only the noble gas undergoes the hp procedure and it is also delivered separately from the molecular host structure. This means that the preparation of the detected spin species happens entirely in the gas phase, followed by dispersion of Xe into the solution or sample of interest. The first step occurs via spin exchange optical pumping (SEOP) to transfer spin polarization from alkali metal vapor electrons (typically Rb) to Xe nuclear spins that are in transient contact with the alkali metal. Modern powerful laser systems (emission at 795 nm for the Rb D$_1$ transition) enable spin polarization between 20% and almost 100%.
4. Signal Transfer Detection Concepts for Xe

Although the preparation of Xe as a hp spin system provides a significant signal enhancement, the nuclei are not necessarily detected directly in a conventional NMR spectrum. Especially for studies with Xe dissolved in solutions containing other molecules of interest, the interactions of Xe with other nuclei might provide routes of signal transfer detection that also come with enhancement. This can include polarization transfer from protons with a larger Zeeman splitting or, vice versa, from hp Xe onto nearby nuclei. Another option is the signal transfer between multiple Xe pools that differ by chemical shift and exist as an abundant pool for detection that is in chemical exchange with dilute pools representing interaction partners of Xe. The latter method is called chemical exchange saturation transfer (CEST), which is also a widely used method in $^1$H NMR and MRI.

5. Aspects of $^{129}$Xe Biosensor Design

The key elements of Xe biosensors comprise the Xe host, a tether or spacer, and the ligand for a certain molecular target [16]. The development focusing on certain building blocks fostered strategies in which these units are typically combined on a scaffold or backbone and often include a fluorophore for cytometry to check for binding specificity (see Figure 1a). Peptide synthesis concepts are often used for the coupling but modular approaches as illustrated in Figure 1b are also an option. Many of the early known Xe interaction partners show an unspecific binding and/or rapid exchange with no dedicated NMR resonance of bound Xe that can be used for CEST detection. The observation of reversible formation of a Xe@cryptophane inclusion complex in solution [24] fostered the idea to further develop this concept into a sensing platform. Cryptophanes with their tailored cavity sizes have thus been used in many sensor designs as starting material for coupling with binding motifs for different biological targets [15][25][26][27][28][29]. Further development of the HyperCEST approach, however, showed that there are other hosts with better Xe exchange dynamics [30][31][32][33].

![Figure 1. Strategies for obtaining functionalized Xe sensors. (a) A Xe host and targeting unit can be coupled to a (peptidic) scaffold via peptide synthesis at activatable tethers (orange). An optional dye label enables combined fluorescence and MRI specificity tests. (b) In a modular approach, a functionalized precursor (e.g., an avidin-activated binding motif) can be delivered to the target. Subsequent delivery of biotinylized Xe hosts and dyes yields the complete sensor.](image)

6. Quantitative Analysis of $^{129}$Xe Host Systems

In many studies, NMR and MRI are used as analytical tools where differences in signal intensities are observed but not necessarily analyzed to obtain absolute numbers for certain physical or chemical
advancements, irrespective of being void space imaging or dissolved gas detection that ultimately also

advancement on DNP led to successful clinical trials, e.g., [1,13C]-pyruvate trial in prostate cancer patients

and its further translation into clinical routine

A critical point for the translation of the HyperCEST technique to (pre-)clinical applications is that this

technique requires a certain time frame for building up the actively driven signal loss. A key component for
future in vivo studies is thus the incorporation of host structures that provide a rather efficient exchange
for optimum CEST effect. Additionally, clinical experience with MRI of dissolved Xe beyond lung tissue is
still an emerging field of research that leaves room for improvement. Although improvements in SEOP
setups and

bio-carriers might facilitate the further translation, a successful demonstration of the Xe
biosensor imaging at the desirable low concentrations in a pre-clinical setting is still lacking.

In preclinical studies, hp

MRI has been utilized to validate different lung disease models, e.g.,
radiation induced lung injury (RILI), fibrotic lung tissue, elastic models of emphysema, asthma models,
brain perfusion etc., noninvasively compared to tissue histology. By utilizing the sensitivity provided by hp

MRI, the progress or changes in the disease patterns are monitored longitudinally in a more
controlled way. Clinical lung imaging with Xe is already quite established and provides great anatomical
and functional information

It also served as a stepping stone for advanced clinical applications for
mapping the Xe distribution in other organs like the human brain

as well as Xe MRI of the kidneys

Additionally, hp

MRI in the clinical side faces challenges similar to that of hp

MRI, e.g.,
requiring optimization of dedicated RF coils for signal transmission/reception. Further, to sustain a longer

technical components such as modern polarizers including high-performance laser diodes

optimized RF antenna systems

and adapted readout protocols. Any Xe MRI application benefits from such advancements, irrespective of being void space imaging or dissolved gas detection that ultimately also
enables (pre)clinical biosensor studies. Recently, \(^{129}\)Xe was utilized for the first time to quantify the gas exchange defects in a rat model of pulmonary hypertension \([49]\). Similarly, another (pre)clinical study reported the in vivo observation of \(^{129}\)Xe HyperCEST responses after administering Sprague-Dawley (SD) rates with unfunctionalized CB[6] at millimolar concentrations \([50]\). Although this preliminary study provided insights on possible Xe distribution in highly perfused areas and nonspecific CB[6] accumulation in different organs, still there is a need for further improvements, e.g., MR sequence optimization, Xe carrier functionalization etc. to facilitate faster clinical translation. Such preclinical approaches might lead to testing different \(^{129}\)Xe biosensors in vivo subsequently and to moving forward to the demonstration of molecular imaging applications of such probes. The full potential of \(^{129}\)Xe NMR/MRI is not yet realized in the clinical stage due to an ongoing accumulation of sufficient and profound translation knowledge related to several components, including organ perfusion with Xe, polarizer optimization for CEST applications, biosafety of biosensors, pharmacokinetics etc. Compared to the other hp NMR techniques, the big advantage of Xe biosensors is the separate delivery of functionalized host units and hp nuclei. Figure 2 illustrates how this decoupling of the time scales for sensor delivery and hp lifetime immensely broadens the applications of hp MRI beyond metabolic imaging and will remain a driving force for further Xe biosensor development. The convenient timing for defining a diagnostic window together with simulations for highly efficient HyperCEST agents \([51]\) pinpoint the way for diagnostic applications of functionalized Xe.

![Figure 2](image)

**Figure 2.** Translation of functionalized Xe to in vivo studies. The sensor is applied systemically and can accumulate in target tissue while wash-out occurs in the surrounding tissue. The decoupling of the time scales allows to perform the more time-sensitive detection of hp \(^{129}\)Xe in a second step. The hp \(^{129}\)Xe can be delivered via inhalation and visualized in other highly perfused organs such as the brain.

## 8. Conclusions

The applications of hp \(^{129}\)Xe nowadays go far beyond gas phase NMR/MRI. Since the pioneering work undertaken at UC Berkeley almost 20 years ago, the Xe biosensor concept has been constantly expanding. Advancements from Xe MRI in general (driven by lung imaging applications) and the overall success of the CEST approach in MRI have made important contributions to further pursue this diagnostic approach. The community is small but making important progress, as illustrated during regular meetings like the XeMat conference \([52]\). Neighboring disciplines like chemical engineering are invited to further promote this concept. At the same time, the sensing options with reversibly bound, hp \(^{129}\)Xe could make novel contributions to characterize emerging materials like MOPs/MOFs or discover weak interactions in supramolecular systems. Taken together, the perspectives for detecting “functionalized Xe” with the HyperCEST method are promising for interdisciplinary work. Its high sensitivity can address previously inaccessible molecular systems, and this will continue to make NMR and MRI important analytical tools throughout the natural sciences and biomedical research communities.
