Properties of Bioactive Glass

Subjects: Biomaterials
Submitted by: Dinesh Rokaya

Abstract

Bioactive glass (BAG) consist of known biocompatible and bioactive minerals, including fluorapatite (FAP), wollastonite, diopside, and tricalcium phosphate. A bioactive material can interact with the biological environment to elicit a specific biological response and they can be osteoconductive or osteoinductive. Bioactive Glasses are amorphous solids with the irregular organization of atoms, optically transparent, and brittle consisting of silica networks. They possess bioactivity and antimicrobial properties as presented in following sections. The bioactivity of BAGs involves several steps; BAGs immediately undergo ionic dissolution and glass degradation via the exchange of H\(^+\) ions in the solution and Na\(^+\) and Ca\(^{2+}\) from the glass network. BAG exhibits antimicrobial properties against various pathogens, e.g., pathogens associated with sinusitis and osteomyelitis.

1. Bioactivity of Bioactive Glass

Glasses are amorphous solids with the irregular organization of atoms, optically transparent, and brittle consisting of silica networks and are, therefore, often termed supercooled liquids. Conventional glasses and BAGs differ in one aspect, their rate of dissolution. Conventional glasses, in general, are expected to have high durability and thus low dissolution rates. BAGs require specific dissolution rates for bioactivity. This is achieved by the addition of network modifiers, such as CaO and NaO, to make the surface and silica network more reactive. From glass dissolution to the formation of hydroxyapatite, bioactivity involves several steps. BAG immediately undergo ionic dissolution and glass degradation via the exchange of H\(^+\) ions in the solution and Na\(^+\) and Ca\(^{2+}\) from the glass network. BAG exhibits antimicrobial properties against various pathogens, e.g., pathogens associated with sinusitis and osteomyelitis.
layer on top of the bulk glass. On top of the gel layer, a layer of amorphous calcium phosphate forms. Precipitation and further mineralization occur due to the incorporated carbonate ions from the now supersaturated solution, thus the concentration of Ca- and Si-ions in solution are critical; about 88–100 ppm and 17–20 ppm of the respective ions are required. The newly formed hydroxyapatite enables growth factors to adsorb to the surface, as well as attachment, proliferation, and differentiation of osteoprogenitor cells by cytokines and extracellular matrix components expressed by the upregulation of several genes[^11]. Although the tissue bonding properties of the BAG are still not precise, collagen and glycoproteins are believed to incorporate the surrounding bone tissue into the hydroxyapatite layer. As the hydroxyapatite grows inwards, the BAG starts to resorb and gets replaced by growing bone tissue[^12]. The glass particles usually have a size of 90–170 μm, which affects their resorption rate. Particle sizes < 150 μm readily degrade as orthosilicic acid is released during the formation of the gel layer. Osteoclasts, once incorporated in the growing bone, break down larger particles[^13] resulting in a more extended period of resorption and stronger bone[^14].

### 2. Antimicrobial Properties

Dental implants or prosthetic joints are surgically inserted to replace lost tissue and increase the function and quality of life of the patients[^15]. However, implants carry a risk of developing infections such as peri-implantitis (PI) or periprosthetic joint diseases (PJI). These infections result in increased morbidity and mortality, as well as resorption of surrounding bone tissue and eventual loosening of the implant. Tomasi and Derks[^16] estimated a weighted mean prevalence of 22% for PI. Any artificial joint may develop PJI. PJI occurs in 0.2–9% of prostheses and is one of the most frequent indications of revision and replacement of the joint prosthesis making up for 15% of hip prostheses and 25% of knee prostheses[^17]. Infection occurs due to the establishment of bacterial biofilm on the surface of the implant. Biofilm is a layer of microbial communities adhering to a surface via a robust polysaccharide matrix and is known to be about a thousand times more resistant to antibiotic (AB) therapy compared to planktonic bacteria. Bone infections pose an additional challenge of the reduced local effect of antibiotic treatment owing to insufficient vasculature[^18] or areas of devitalized bone[^19]. Additionally, the increasing prevalence of antibiotic-resistant bacteria, including multidrug-resistant bacteria, results in the ineffective treatment of bacterial infections with antibiotic therapy, including AB-loaded bone substitutes as carriers[^20]. Surgical debridement or osseous resection followed by placement of a bone substitute in the defect has shown positive treatment outcomes for established PI cases. PJI can be managed by surgical debridement and AB therapy. However, for resistant pathogens or loosened prosthesis, revision is necessary, which results in reduced quality of life[^21].

BAGs, specifically BAG-SS3P4, have shown to possess broad-spectrum antimicrobial properties with no observed resistance to date[^22]. *S. aureus* is among the most common bacterial strains implicated in PJIIs and a major biofilm contributor. However, SS3P4 has proved to reduce the biofilm mass in vitro conditions[^23][^24]. The antibiofilm activity has further been observed to affect several multi drug resistant strains isolated from PJIIs[^25]. Additionally, an increased antibiofilm effect is observed with the incorporation of antimicrobial molecules into the BAG[^26][^27]. SS3P4 has successfully been used in the treatment of osteomyelitis[^28]. The antimicrobial and antibiofilm effects of bioactive glasses differ from that of conventional Abs, as once embedded in the body, bioactive glasses increase the pH and osmolarity locally, which creates an environment unfriendly for bacterial growth and adhesion[^25][^29]. Bari et al.[^30] developed Cu-doped mesoporous SiO$_2$-CaO glass (Cu-MBG) by an ultrasound assisted one-pot synthesis (Figure 1). Cu-MBG nanoparticles showed antibacterial effects against 3 bacterial strains (*E. coli*, *S. aureus*, and *S. epidermidis*). The Cu-MBG can be a promising and versatile platform for bone and soft tissue regeneration.
As alkalinity is considered the primary antimicrobial mechanism, Bioglass® 45S5 is considered more effective. However, S53P4 presents a more delicate balance between antimicrobial properties, alkalinity with a pH of 7.9, and osteogenicity.[30] Particle size influences the antimicrobial properties as well; small particle sizes increase the surface area and the antimicrobial effect.[24][31] Alkali-free BAG doped with ZnO and SrO synthesized by melt quenching exhibited antimicrobial properties against strains of *Staphylococcus aureus* and *Escherichia coli*. The results suggest that BAGs can still provide antimicrobial properties in the absence of alkalinity.[23] These properties make BAG perhaps the ideal bone substitute in the treatment of bone infections such as osteomyelitis and peri-implant infections.[33][34] The US Food and Drug Administration (FDA) has approved Bioglass® 45S5 and S53P4 for clinical applications where antimicrobial properties are desired.[25]

BAG also exhibits antimicrobial properties against pathogens associated with sinusitis, which makes it excellent for sinus augmentation and repairing of the orbital floor defects. A communication often exists between these anatomical structures, and infection from maxillary sinus can quickly spread to an orbital floor implant, necessitating implant removal.[36] Hence, BAG S53P4 can be used for these applications due to slow resorption and antimicrobial effect.

BAG-coated dental implants have shown promising results with reduced bone loss in experimentally induced PI in beagle dogs.[37] A recent in vitro study showed reduced biofilm formation of putative periodontal pathogen strains, in addition to *S. mutans*.[38] Besides, reduced growth of periodontitis-associated and cariogenic bacteria, as well as *Enterococcus* facials, has been reported using BAG containing propolis, a naturally occurring compound in beehives.[39] Additionally, BAGs can incorporate hydrophilic as well as hydrophobic compounds into their structure suggesting several
undiscovered combinations of compounds may be achievable to increase antimicrobial efficiency, strengthening a future antimicrobial role of bioactive glass in dental applications. Another assessment was done on machined Ti6Al4V threaded dental implant coated with hydroxyapatite and bioactive glasses in human jaws, the outcome is very promising and futuristic. The observed BAGs are safe and effective like hydroxyapatite for enhancing osseointegration.
